

The values I used in my eval function were the difference between moveable pieces for the player and their opponent and the difference between the number of moves the player and their opponent could make. When subtracting the opponents moves from the player's possible moves I doubled the value for opponent moves in order to give it more weight. I did this because when left alone MinimaxPlayer with a depth of 1 won when they went second. Another reason I did this is because the victory condition is when the opponent can no longer make any moves regardless of how many pieces each player has. Another part of my eval function was to force a move when an opponent's possible moves from a given state was 0 by returning positive infinity.

I also considered the number of pieces each player had in the corner of the board and the difference between the player's pieces and the opponent's pieces. I looked at the corner pieces because I thought those positions were the most protected, but ended up removing that part because the number of pieces each player has does not come into play when determining a winner. Corner pieces also have less available moves which makes them less valuable. The other part of the function was not completely removed, but I changed it from counting the number of pieces to the number of moveable pieces each player has. I made this change because once a piece is no longer able to move it becomes useless so it is better to not consider them when evaluating.
